ABSTRACT: Manipulation of spin degree of freedom (DOF) of electrons is the fundamental aspect of spintronic and valleytronic devices. Two-dimensional transition metal dichalcogenides (2D TMDCs) exhibit an emerging valley pseudospin, in which spin-up (-down) electrons are distributed in a +K (−K) valley. This valley polarization gives a DOF for spintronic and valleytronic devices. Recently, magnetic exchange interactions between graphene and magnetic insulator yttrium iron garnet (YIG) have been exploited. However, the physics of 2D TMDCs with YIG have not been shown before. Here we demonstrate strong many-body effects in a heterostructure geometry comprising a MoS\textsubscript{2} monolayer and YIG. High-order trions are directly identified by mapping absorption and photoluminescence at 12 K. The electron doping density is up to ∼10\textsuperscript{13} cm\textsuperscript{-2}, resulting in a large splitting of ∼40 meV between trions and excitons. The trions exhibit a high circular polarization of ∼80\% under optical pumping by circularly polarized light at ∼1.96 eV; it is confirmed experimentally that both phonon scattering and electron–hole exchange interaction contribute to the valley depolarization with temperature; importantly, a magnetoresistance (MR) behavior in the MoS\textsubscript{2} monolayer was observed, and a giant MR ratio of ∼30\% is achieved, which is 1 order of magnitude larger than the reported ratio in MoS\textsubscript{2}/CoFe\textsubscript{2}O\textsubscript{4} heterostructures. Our experimental results confirm that the giant MR behaviors are attributed to the interfacial spin accumulation due to YIG substrates. Our work provides an insight into spin manipulation in a heterostructure of monolayer materials and magnetic substrates.

KEYWORDS: magnetic heterostructures, spintronics, valleytronics, valley polarization, 2D materials
WSe₂ is half a unit cell of the bulk crystal and thus induces the breaking of space-reversal inversion symmetry. Two sublattices are occupied by one transition metal atom and two chalcogen atoms in the honeycomb lattice structure, thus generating a local in-plane electric field. Equations have rise to optical selection rules for interband transitions at the +K (−K) momentum valley and the valley Hall effect. The spin-up (−down) electrons and spin-down (−up) holes mostly exist in the +K valley. The orbital magnetic moment \( \mu_a \) of electrons (holes) in the conduction (valence) band, and \( \mu_B \) is the Bohr magneton, \( r = \pm 1 \) for the \( ± K \) valleys, \( s_z \) is the spin in the \( z \) direction, \( \alpha = m_e/m^* \), where \( m^* \) is the effective mass of electrons (holes) in the conduction (valence) band, and \( \Delta \alpha = \alpha_z - \alpha_e \). Thus, the band gap should be increased in the +K momentum valley under a positive magnetic field \( B > 0 \), and contrarily decreased in the −K momentum valley, \( B < 0 \), and the band gap shift \( \Delta E = \mu_B = -(2 - \Delta \alpha) \mu_B B \). The magnetic manipulation of valley splitting, however, is only feasible under high external magnetic field \( B = 7 \) T.\(^{11} \)

The interfacial magnetic exchange field can enhance the interaction of the total magnetic moment of electrons with the external magnetic field. Equations have rise to the strong magnetic proximity effects, imparting ferromagnetic properties and an anomalous Hall effect in graphene, WSe₂, and Pt films. However, the low Curie temperature \( T_C \approx 15 \) K and large saturation magnetization \( (M_s = 2) \) inherent in EuS thin films limit practical applications. The \( T_C \) of YIG films is above room temperature and the \( M_s \) is \( 0.2 \) T, which is critical for spin manipulation at high temperature and low magnetic field.\(^{15} \) However, the interface physics of 2D TMDGs with YIG films have not been explored before. This raises two fundamental questions in the MoS₂/YIG heterostructure: (1) How do the YIG magnetic substrates affect the photoluminescence (PL) and valley polarization of a MoS₂ monolayer? and (2) do the magnetoresistance effect and interfacial magnetic exchange field take place in the MoS₂ monolayer? Moreover, in theory, the valley-spin relaxation originates from the electron–hole exchange interaction;\(^{20–22} \) however, few experimental reports exist on the relaxation mechanism of valley polarization as a function of temperature.\(^{23} \) Here we investigate the optical response and valley polarization of monolayer MoS₂ in a MoS₂/YIG heterostructure by means of absorption and photoluminescence spectroscopy. We demonstrate that the high electron doping of \( \sim 10^{13} \) cm⁻² gives rise to the trions in the whole MoS₂ monolayer. The splitting between trion resonance and neutral exciton A resonance is distinct below 170 K, which is \( \sim 40 \) meV. The valley polarization of trions is \( \sim 80\% \) at 12 K. Our results experimentally demonstrate that the synergy of phonon-assisted intervalley scattering and electron–hole exchange interaction contributes to the valley depolarization with increasing temperature. Importantly, a giant magnetoresistance (MR) ratio of \( \sim 30\% \) is observed in MoS₂/YIG heterostructures. Both valley polarization and linear Hall resistance results exclude the possibility of an interfacial magnetic exchange interaction; thus the MR behaviors originate from the spin accumulation at the interface of the MoS₂ monolayer and YIG substrates.

RESULTS AND DISCUSSION

Trions in the MoS₂/YIG Heterostructure. In our investigation, MoS₂ monolayers were mechanically exfoliated from bulk crystal onto polydimethylsiloxane (PDMS) films and transferred onto \( \sim 60 \) nm YIG films on a Si substrate. The MoS₂/YIG heterostructure is shown in Figure 1b and c. The Raman in-plane \( E_{2g} \) mode and out-of-plane \( A_{1g} \) mode of the exfoliated...
MoS$_2$ monolayer are at 383.3 and 401.8 cm$^{-1}$, respectively (Figure 1d). The energy difference between $E_{2g}$ and $A_{1g}$ modes is used extensively in the literature as the fingerprint of the number of layers, in this case the energy difference between the $E_{2g}$ and $A_{1g}$ is 18.5 cm$^{-1}$, confirming that MoS$_2$ is a monolayer. The YIG film is pure polycrystalline garnet phase (Supplementary Figure S1). The out-of-plane (hard axis) and in-plane (easy axis) $M_s$ of the YIG films are $\sim$0.2 and 0.01 T at room temperature (Figure 1e), respectively, which highlights the feasibility of applying a low magnetic field toward the interfacial magnetic exchange field at high temperature.

The optical absorption spectra of an atomically thin monolayer allow us to gain an understanding of the basic features of the exciton in the MoS$_2$/YIG heterostructure. The strong spin−orbit coupling of the electrons in d-orbitals of the metal atoms results in the splitting of the valence band at the K points, giving rise to exciton A and B resonances in the band-edge transition. Figure 2a shows the typical absorption spectra of a MoS$_2$ monolayer as a function of temperature in the range of 12−290 K. It shows three pronounced absorption features at 12 K. The feature at 2.08 eV is associated with direct optical transitions of B excitons. Because of the electron doping, two peaks at 1.97 and 1.93 eV are identified, which are attributed to neutral A exciton resonance and a negatively charged trion resonance, respectively. To further validate the trions in the MoS$_2$ monolayer, microabsorption mapping was performed at 12 K. All optical absorption measurements were carried out in a vacuum with $\sim$500 nm spatial resolution in the photon energy range of 1.6−2.2 eV. Figure 2b−d show the corresponding absorption intensity image of the trion, exciton A, and exciton B at 12 K, which visualize that the MoS$_2$ monolayer is homogeneously doped by electrons (Supplementary Figure S3a), giving rise to a trion accompanied by exciton A and exciton B across the whole MoS$_2$ monolayer. Below 170 K, the absorption features of trion and exciton A are distinct, which however are broadened as the temperature increases and become almost indistinguishable above 190 K (Figure 2a and Supplementary Figure S2). All three absorption resonances of the trion, exciton A, and exciton B are red-shifted as the temperature increases, which contributes to the interaction of electrons with optical phonons resulting from the high-frequency Bose−Einstein oscillations, in which $E(T)=E_0+2\Delta/(\exp(E/k_B T)-1)+A_T$, where $E_0$ is the average energy of the Bose−Einstein oscillators corresponding to the optical phonons (Supplementary S3). The temperature variation of the trion, exciton A, and exciton B can be well fitted by the Bose−Einstein oscillator model (Supplementary Figure S3b). The average energy of the optical phonons of the MoS$_2$ monolayer is $\sim$23 ± 4 meV. The splitting $\Delta E_{\text{exc}}$ between the trion and exciton A is $\sim$40 ± 2 meVs, which is almost independent of the temperature (Supplementary Figure S3b). Furthermore, to verify the electron doping from YIG substrates, we studied the absorption properties of the MoS$_2$ monolayer on PDMS substrates, which are used to exfoliate the corresponding MoS$_2$ monolayer (Figure 2e). The exciton A and B features are clearly detected; however, no detectable trion feature is observed; this indicates that YIG substrates contribute to the electron doping toward the trions. We speculate that the electron doping for trions may be due to the oxygen dangling bonds on the surfaces of YIG substrates (Y$_3$Fe$_5$O$_{12}$).

**Valley Polarization of Trions.** The temperature dependence of trion PL intensity yields insight into the trion binding energy. We photoexcite a MoS$_2$/YIG heterojunction by a right-hand ($\sigma^+$) and left-hand ($\sigma^-$) circular polarized laser at 1.96 eV, giving rise to a right-hand ($\sigma^+$) and left-hand ($\sigma^-$) circular

![Figure 2. Electronic structure of the MoS$_2$ monolayer. (a) Absorption spectra of the MoS$_2$ monolayer as a function of temperature in the range of 12−290 K. The trion and exciton (A and B) resonances are noticeable and clearly distinguishable. (b, c, d) Absorption maps of trion and exciton (A and B) resonances of the MoS$_2$ monolayer on a YIG substrate at 12 K. This unambiguously demonstrates that trion resonances are uniformly formed in the MoS$_2$/YIG heterostructure. (e) Absorption spectra of the MoS$_2$ monolayer on PDMS substrates as a function of temperature, which do not offer any detectable trion feature.](image-url)
emission. It should be noted that the excitation energy is smaller than the A exciton resonance energy below 90 K (Supplementary Figure S3b). Figure 3a shows the right-hand PL and corresponding absorption spectra of the MoS2 monolayer in a MoS2/YIG heterojunction at 12 K. The PL peak at \( \sim 1.93 \) eV matches the trion absorption resonance in both its position and width. Therefore, we attribute the PL emission to the trions. The evolution of the trion emission energy as a function of the temperature under a right-hand circular polarized laser at 1.96 eV with 1.5 mW is plotted in Figure 3b,c. As the temperature increases from 12 K to 290 K, the PL peak energy monotonically decreases from 1.93 eV to 1.85 eV. The trion binding energy \( \Delta E_{\text{trb}} \) is estimated to be \( \sim 17 \pm 2 \) meV (Supplementary Figure S4), which is comparable with the reported value. The two PL peaks at 1.92 and 1.94 eV become weak as the temperature increases and are almost indistinguishable and disappear above 150 K. We suggest thus that the PL emission at 1.92 and 1.94 eV may be due to the defects in the MoS2 monolayer. The trion binding energy \( \Delta E_{\text{trb}} \) is predicted to obey \( \Delta E_{\text{trb}} = \Delta E_{\text{ex}} - 0.5(m_e/m_h)E_p \), where \( m_{e/h} = m_e + m_h \), and \( m_{e/h} = 1.13m_0 \) and \( m_{e/h} = 0.78m_0 \), where \( m_0 \) is the effective mass in units of electron mass of the MoS2 monolayer. Thus, the Fermi energy \( E_f \) is \( \sim 67 \) meV in the MoS2/YIG heterojunction. In atomically thin 2D materials, the size confinement and weak screening result in a dramatically enhanced exciton effect, electron–electron interactions, and Coulomb interactions. The Coulomb potential for electrons and holes separated by a distance \( r \) is defined by \( V_{\text{Coul}}(2D) \propto -\frac{1}{2} \ln \left( \frac{r}{r_0} \right) + (\gamma - \ln 2) e^{-r/r_0} \), where \( r_0 \) is the screening length, which is \( \sim 3\text{–}4 \) nm in 2D materials, and \( \gamma \) is the Euler’s constant, \( \sim 0.5772 \). Importantly, the dimensionless strength of the charge interactions, \( r_{\text{eff}} \), can be considered to be the ratio of Coulomb potential to kinetic energy, which is given by \( r_{\text{eff}} = 2/\sqrt{n_0} \). Thus, the Coulomb potential of the MoS2 monolayer is an order of magnitude larger than that of 2DEG system at the conventional heterojunctions, which also increases as a function of electron density (Supplementary S5, Figure S5). To clearly compare with recently reported results, we still use the Fermi level equation from ref 31, \( E_f = \hbar^2 \pi n_s/2m_e^* \), although which is more appropriate for a 2D electron gas in GaAs semiconductor heterojunctions; the electron density \( n_s \) is thus estimated to be \( \sim 1.0 \times 10^{13} \text{ cm}^{-2} \), which is comparable with the reported value achieved under an 80 V gate voltage. However, it should be noted that the effective electron mass \( m_e^* \) is from the MoS2 monolayer, and thus the obtained \( n_s \) can still be used to measure the electron density in the MoS2 monolayer to some extent.

Further, our polarization-resolved PL shows that the luminescence of trions conserves valley polarization. The right and left circularly polarized luminescence spectra of trions in a MoS2/YIG heterostructure at 12 K are shown in Figure 4a and b, respectively. Under the right-hand circular polarized \( (\sigma^-) \) excitation at 1.96 eV with 1.5 mW, the \( P(\sigma^-) \) is much larger than \( P(\sigma^+) \), and the degree of circular polarization \( \eta \) is \( \sim 70\% \), which is defined as \( \eta = (P(\sigma^-) - P(\sigma^+))/(P(\sigma^+) + P(\sigma^-)) \).
exchange interaction, contributes to the spin-polarization $\eta$, valley- and spin-scattering, which allows a hole spin to relax by a simultaneous dependence of splitting (0.5 strongly suppressed for spin relaxation, and the large spin $\eta$ polarization which decreases as the temperature increases (Supplementary S6, Figure S6). Below 30 K, the $\eta$ mapping of left-hand ($70\%$ substrates at 12 K, which indicates that the system is in excellent calibration. The inset in (a) is a two-dimensional image of the degree of circular polarization of the trions. The inset represents the spin relaxation.

Figure 4c show the temperature dependence of the degree of polarization $\eta$ under right-hand circularly polarized excitation, which decreases as the temperature increases (Supplementary S6, Figure S6). Below 30 K, the $\eta$ is nearly temperature independent with a similar value. In the MoS$_2$ monolayer, the Elliot–Yafet (EY) mechanism and the Dyakonov–Perel (DP) mechanism are strongly suppressed for spin relaxation, and the large spin splitting (0.5–1 eV) inhibits the intravalley spin flip.\(^{20}\) The Bir–Aronov–Pikus (BAP) mechanism, which is due to the e–h exchange interaction, contributes to the spin-flip and intervalley scattering, which allows a hole spin to relax by a simultaneous valley- and spin-flip scattering with the electrons. The circular polarization $\eta$ is equal to $P(\sigma^-)/\left(1 + 2\tau_{AS}/\tau_{AS}\right)$, where $\tau_{AS}$ is the PL lifetime and $\tau_{AS}$ is the intervalley relaxation time of the trions (Figure 4d, inset). It is supposed that the intervalley electron–hole exchange interaction contributes to valley depolarization; on the other hand, the intervalley scattering involved in the Coulomb potential, phonons, and impurities also results in the valley depolarization.\(^{21,22}\)

It is hypothesized that the intervalley scattering relaxation rate $1/\tau_{AS}$ is proportional to both the phonon population $1/e^{\hbar\omega/k_BT}$ and the electron–hole exchange interaction $k_BT(2m\hbar^2/k_BT)^{1/2}$; the radiative lifetime of trions obeys a monotonically increasing relation with increasing temperature, $\tau_{AS} \propto k_BT;\(^{20,40}\)$ on the contrary, the nonradiative time decreases with temperature, $\tau_{NRA} \propto e^{\hbar\omega/k_BT}$.\(^{34,43}\) The lifetime of trions thus is given by $1/\tau_{AS} \propto 1/k_BT + e^{-\hbar\omega/k_BT}$. We anticipate that the intervalley spin relaxation may be due to the combination of various mechanisms described above to some extent; thus the temperature variation of the degree of circular polarization of the trions is well fitted by $\eta \propto 1/(1 + bT/(e^{\hbar\omega/k_BT} + \gamma T))$ and $\alpha = 3.1$, which is close to the theoretical parameter of 2.5 (Figure 4d). Thus, the synergy of electron–hole exchange interaction and phonon scattering determines the temperature variation of valley polarization. It should be noted that the energy difference between the excitation laser (1.96 eV) and the trion resonance also increases as the temperature increases (Supplementary Figure S3b), which may also contribute to the decrease of valley polarization.\(^{20}\)

The magnetic moment depends on the exchange coupling strength of different atoms from YIG and the adjacent layer. The YIG termination layer and defects contribute to the interfacial magnetic exchange, which also determines the electronic and magnetic properties of the adjacent layer, such as Pt and graphene.\(^{46}\) We thus investigate the valley Zeeman splitting in heterostructures comprising a MoS$_2$ monolayer and YIG, GaMnAs, Eu-doping YIG, and YIG treated by Ar and O$_2$ plasma.
under a magnetic field of ±0.2 T at 12 K. However, there is no distinguished difference between the right- and left-hand PL emission spectra (Supplementary S7, Figure S7). The first-principles calculation results show that the Zeeman splitting of MoS2 can be neglected in a van der Waals heterostructure comprising a MoS2 monolayer and a YIG terminated by a crystalline plane (111) consisting of tetrahedral and octahedral Fe3+ and Y3+ ions (Supplementary S8, Figure S8). Thus, we suggest that the Zeeman-type splitting is too weak to be observed in the MoS2/YIG heterostructures at 0.2 T magnetic fields.

To validate interfacial spin interaction of a 2D TMDC monolayer and YIG magnetic insulator, the magnetoresistance of a MoS2 monolayer on YIG substrates is studied at 1.5 K. As shown in the insets in Figure 5a and b, the longitudinal resistance of a MoS2 monolayer and a YIG terminated by a crystalline plane (111) consisting of tetrahedral and octahedral Fe3+ and Y3+ ions (Supplementary S8, Figure S8). Thus, we suggest that the Zeeman-type splitting is too weak to be observed in the MoS2/YIG heterostructures at 0.2 T magnetic fields.

To validate interfacial spin interaction of a 2D TMDC monolayer and YIG magnetic insulator, the magnetoresistance of a MoS2 monolayer on YIG substrates is studied at 1.5 K. As shown in the insets in Figure 5a and b, the longitudinal resistance of a MoS2 monolayer and a YIG terminated by a crystalline plane (111) consisting of tetrahedral and octahedral Fe3+ and Y3+ ions (Supplementary S8, Figure S8). Thus, we suggest that the Zeeman-type splitting is too weak to be observed in the MoS2/YIG heterostructures at 0.2 T magnetic fields.

Recently, negative MR behaviors have been observed in Dirac semimetal Cd3As2 nanowires and ribbons,47,48 TaSb2,49 and ZrTe5,50 and Weyl semimetals TaAs51 and few-layer WTe252 due to the chiral anomaly effect and the weak localization. However, no detectable MR behavior is observed in a single-crystal MoS2 monolayer on Si/SiO2 substrates (Figure 5a),54 which indicates that the chiral anomaly, weak localization, and nanodomain boundary effect can be ruled out in the MoS2/YIG heterostructures. It should be noted that the YIG and SiO2 films are insulator materials, which cannot divert the electron current away from the MoS2 monolayer; thus we speculate that the variation of resistance of the MoS2 monolayer as a function of magnetic field is due to the interface spin interaction in MoS2 and YIG. Generally speaking, two possible physical mechanisms determine the MR behaviors: (1) the induced magnetic moment by interfacial magnetic proximity effect; (2) accumulated spin at the interface, in which the spin-current is coupled with the electron current, leading to the resistance change. Since the right-hand and left-hand circularly polarized PL spectra are almost totally overlapped under a magnetic field correlated with the saturation magnetization of YIG (Figure 1e), this indicates that no magnetic proximity effect takes place at the interface of the
MoS₂ monolayer and YIG. The Hall effect measurements show a linear ordinary Hall resistance behavior (Figure 5b), which also indicates that proximity-induced magnetism can be ruled out, consistent with the polarization-resolved PL results. Thus, we attribute the negative MR behavior to the interfacial spin accumulation due to YIG.

To obtain an understanding of interfacial spin interaction mechanism, ferromagnetic resonances (FMR) were carried out in shorted waveguides and cavities. Figure 5c shows the FMR absorption derivative profiles of bare YIG and MoS₂/YIG heterostructures obtained with an 8.0 GHz cavity. The thickness of the YIG layer in both samples is tuned to be 5 nm for facilitating the observation of interfacial interaction. The FMR line-width (ΔH) is assigned to be the peak-to-peak line-width of the FMR absorption derivative profiles, which is given by $\sqrt{3\Delta H = 2\alpha|f| |\gamma| + \Delta H_{0}}$, where $\alpha$ is the effective damping parameter, $f$ is the microwave frequency, $|\gamma|$ is the gyromagnetic ratio, $|\gamma| = 2.8$ MHz/Oe, and $\Delta H_{0}$ represents the line-width inhomogeneity. The FMR peak-to-peak line-widths of YIG (ΔH_YIG) and MoS₂/YIG (ΔH_MoS₂/YIG) are 27.2 and 35.2 Oe, respectively. The larger line-width of MoS₂/YIG indicates an increasing damping and the occurrence of spin pumping and transfer of spin angular momentum between YIG and MoS₂ at the interface. Compared with a ΔH enhancement of 74.2% and 193.5% in graphene/YIG and Pt/YIG, a 29.4% enhancement of ΔH is absolutely observed in our MoS₂/YIG heterostructures, indicating lower but manifest interfacial coupling of spin angular momentum at the interface. The spin pumping is attributed to the interfacial coupling of the MoS₂ monolayer and spins in the YIG films, which results in a torque between MoS₂ and YIG magnetization. This torque leads to an increase of the FMR line-width and simultaneously influences the resistivity and mobility of the MoS₂ monolayer and further results in the giant magnetoresistance. Figure 5d shows the FMR field ($H_{FMR}$) as a function of microwave frequency. The $H_{FMR}$ of MoS₂/YIG and bare YIG are overlapped almost totally, which confirms that no magnetic proximity effect takes place again and may also rule out the static coupling of magnetization at the interface, consistent with the polarization-resolved PL and Hall resistance results. It is thus speculated that the interfacial spin coupling and accumulation contribute to the magnetoresistance behavior. Further systematic studies are needed on the other types of 2D TMDC monolayers (such as CrI₃ and CrₓGeₓTe₃), crystal stacking, defects, and gate voltage, which may play a significant role in defining the magnetic exchange interaction and interfacial spin manipulation.

CONCLUSION

Our studies reveal that the YIG magnetic insulator gives a doping electron density of $\sim 10^{13}$ cm⁻², giving rise to trions in the MoS₂ monolayer; the spin accumulation induces a giant magnetoresistance ratio of $\sim 30\%$ at the interface of the MoS₂ monolayer and YIG films, which derives from the torque due to spin interfacial coupling. The trions show high circular polarization and large binding energy, which may provide possibilities of the manipulation of many-body states of the TMDC monolayer. The electron doping density for trions also can be tuned from $\sim 5 \times 10^{12}$ cm⁻² to $\sim 1 \times 10^{13}$ cm⁻² by electric field under gate voltages from 0 to 80 V. Our YIG was grown on p-doped Si substrates, which is facilitated to further deeply tune the trions to improve the splitting energy, developing integrated optoelectronic and photonic devices.

The time-reversal symmetry of 2D TMDCs is broken under optical excitation by circularly polarized light, which gives rise to the valley Hall effect. The 2D TMDCs/YIG heterostructures show potential to give a magnetic freedom to manipulate the electron spin for spintronic and valleytronic devices by spin and valley Hall effects. Recently, YIG was shown to be an ideal material for spin-wave spin-currents, although it is an insulator for electric currents. The spin-wave spin-current is injected from the YIG layer into the Pt layer, in which the spin-current is converted into an electric voltage perpendicular to the spin polarization direction via spin–orbital coupling. Therefore, the 2D TMDCs/YIG heterostructures are a promising geometry toward spin-wave spin-current devices.

EXPERIMENTAL METHODS

Sample Preparation. MoS₂ monolayer flakes were mechanically exfoliated from bulk crystal onto PDMS films and then transferred onto YIG/Si substrates, which were grown by pulsed laser deposition.

Optical Spectroscopy Measurement. The PL, Raman, and reflection signals were recorded by a Witec Alpha 300R Plus confocal Raman microscope, which is coupled with a closed cycle optical cryostat (10 K) and a XY scanning stage. A long work distance 500x objective (NA = 0.55) was used for the low-temperature PL and reflection measurement. The polarization-resolved PL spectra were obtained under a circular polarization excitation at 1.96 eV of 1.5 mW. The Raman spectra were collected under 2.33 eV laser excitation of 5 mW. The magnetic field of 0.2 T was home-built by a NdₓFe₁₋ₓB permanent magnetism disk with a ~1 cm diameter and ~1.3 mm thickness, and a hole of ~1 mm diameter is at the center of the disk. The sample was put between two NdₓFe₁₋ₓB disks through the hole, which were put in the cryostat.

Magnetoresistance Measurement. The magnetoresistance and Hall resistance measurements were performed in an Oxford Teslatron system at a base temperature of 1.5 K. All resistances were measured by sourcing a DC current of 10 nA with a Keithley 2400 and measuring the voltage signal using a Keithley 6430. A gate voltage of 80 V was supplied with a Keithley 6430.
